COMMUNICATIONS SYSTEM

The present invention relates to radio access bearers which are aligned with both the GSM/EDGE RAN (GERAN) and UMTS RAN (UTRAN).

5

Broadly speaking telecommunications services are divided into two categories these are bearer services and tele services. Bearer services allow a user to access various forms of communications such as asynchronous circuit switched data service interworking with the public switched telephone network (PSTN) or packet switched synchronous data service interworking with the packet switched public data network (PSPDN). Tele services on the other hand allow a user to access various forms of applications such as transmission of speech, short messaging services and facsimile transmissions. Such bearer services are currently adopted in the universal mobile telecommunications system (UMTS). This UMTS network is composed of four sub-networks the access network, the core network, service mobility control network and the telecommunication management network. Of these the access network is responsible for basic transmission and switching functions required to enable a mobile station (MS) to access a fixed network resource over the radio interface (U_m interface).

20

Bearer services (bearers) which allow a user to access various forms of communication over the UMTS radio access network (RAN) are already well defined.

25

An alternative to the UTRAN is GERAN. As GERAN develops new radio access bearers are defined. Since the GERAN will connect to a core network common with UMTS it is required that the bearers offered by GERAN are aligned with those of UTRAN. The following traffic classes are then to be supported in order to fulfil the service requirement. These traffic classes are the types of traffic which will occur over the RAN between the access network and the core network of the mobile telephone system.

30

Conversational Traffic

Real time conversation schemes are characterised by the fact that the transfer time must be low because of the conversational nature of the scheme and the
5 at the same time that the time relation (variation) between information entities of the stream must be preserved in the same way as for real time streams. Therefore the limit for acceptable transfer delay is very strict since failure to provide low enough transfer delay will result in an unacceptable lack of quality. The transfer delay requirement is therefore both significantly lower and more
10 stringent than the roundtrip delay of the interactive traffic case set out below.

Streaming Traffic

This one way scheme is characterised by the fact that the time relations
15 (variation) between information entities (i.e. samples, packets) within a flow must be preserved, although it does not have any requirements on low transfer delay. The delay variation of the end to end flow must be limited, to preserve the time relation (variation) between information entities in the stream.

Interactive Traffic

When the end-user is online requesting data from remote equipment this scheme applies. Interactive traffic is characterised by the request response pattern of the end-user. At the message destination there is an entity expecting
25 the message (response) within a certain time. Roundtrip delay time is therefore one of the key attributes. Another characteristic is the fact that the content of the packets must be transparently transferred (with low bit error rate).

Background Traffic

30

When the end-user sends and receives data files in the background this scheme applies. Examples are background delivery of emails, SMS, download of databases and reception of measured records. Background traffic is characterised by the fact that the destination is not expecting the data within a

certain time. This scheme is thus more or less delivery time insensitive. Another characteristic is that the content of the packet must be transparently transferred (with low bit error rate).

5 The main distinguishing factor between these various traffic classes is how delay sensitive the traffic is. Conversational class traffic is meant for traffic which is delay sensitive while background class traffic is the most delay insensitive traffic class. Conversational and streaming classes are mainly intended to be used to carry real time traffic flows. Interactive class traffic and
10 background traffic are mainly meant to be used by traditional internet applications like WWW, email, telnet, FTP and news. Due to looser delay requirements compared between conversation and streaming classes both provide better error rates by means of channel coding and retransmissions. These traffic classes are further detailed in UMTS 23.107.

15

In view of the common usage of the UMTS core network in the communication protocols used to create GERAN, radio access bearers should also be built as in UMTS where combinations of different modes of protocols in one single stack provide a large set of bearers.

20

Communication protocols are the sets of rules which users adopt when establishing services and transferring data. Protocols permit the setting up and management of connections and are also needed to enable reliable communications. The functions which are provided by the communication
25 protocols are well described but their implementation is not. A model which describes the functions provided by the communication protocols contains several layers. These are called protocol stacks.

Figure 1 shows a user plane protocol stack 10 suitable for use with the GERAN
30 in which each layer includes different modes. The stack includes a physical layer 11 which is analogous to the physical layer of a UMTS access network protocol stack, a media access control (MAC) layer 12 which corresponds to the data link layer of a standard UMTS stack, a radio link control (RLC) layer 13 corresponding to the UMTS stack network layer and a packet data

convergence protocol (PDCP) layer 14 corresponding to the application layer of the UMTS stack model.

If the MS is not fully internet protocol (IP) based or it is desired to use GSM
5 circuit mode one element will have to take care of translation of circuit mode data to/from IP/User Datagram Protocol (UDP)/Real Time Protocol (RTP) packets and translation of 04.08 signalling to/from some IP-based signalling (e.g. H.323). Such a function is most probably only required for conversational and streaming traffic classes. Consider an example, where a data spurt is
10 transmitted between the endpoints of a connection in data packets. The data blocks produced by an application can be encapsulated into data packets of certain transmission protocols. The Real Time Protocol (RTP) is an example of a packet data protocol that can be used for applications which do not tolerate delays. The data blocks are encapsulated into RTP protocol packets by
15 placing the data blocks themselves into a payload of the packets and by adding suitable headers to the data blocks. Some protocols may need some information also in the end of the protocol packet.

The RTP data packets may be transmitted using User Datagram Protocol
20 (UDP), which may be run on Internet Protocol (IP). UDP and IP add their own headers to the data packets. The data packet delivered to a link layer protocol therefore typically consists of the original payload and many headers. The link layer protocol may perform header stripping for example the protocol headers typically contain various fields, whose content does not change from packet to
25 packet. The result of the header stripping is called header stripping residue, and it is the information that needs to be transmitted for a certain packet or group of packets to allow the receiving end to construct the packet headers again. The header stripping can be performed on each data packet similarly, or it maybe performed, for example, on the first data packet and then the content
30 of the headers of the next data packets is determined using the information of the headers of the first data packet.

For the protocol combination RTP/UDP/IP the header stripping result typically contains at least the sequence number (SN) of the RTP packet, the time stamp (TS) of the RTP packet and the marker (M) bit of the RTP packet. It is possible

that only a certain offset of these needs to be transmitted for updating. Information related to the UDP and IP headers can be determined straightforwardly after the first UDP/IP packets of the connection have been transmitted to the receiving end. Once the header stripping residue and the payload of the data packets are transmitted over the radio access network, a network element on the other side of the radio access network can reconstruct the RTP/UDP/IP packets using the header stripping residue and the transmitted payloads. Typically the protocol packets are transmitted without the headers over the radio interface, the network element reconstructing the headers and protocol packet can be, for example, either a mobile station or a base station controller (BSC), depending on the transmission direction. Especially in a receiving mobile station, which typically does not forward the data packets to other network elements, the reconstruction of headers does not have to mean that a data structure corresponding to the header is constructed explicitly. It maybe enough that the header stripping residue and the payload of the data packet is forwarded via the IP/UDP protocol layer to RTP layer. In the IP/UDP layers, for example, only some counters related to the IP/UDP protocol packet sequence number may be incremented.

It would also be advantageous for several radio access bearers to be allowed which could be used simultaneously with single user equipment. This can be used to provide support for multiple quality of service (QoS) profiles in parallel. This helps maintain the communication quality under various traffic conditions.

A number of multiplexing scenarios must also be considered in providing radio access bearers for the GERAN. These are set out below.

Operational Scenario 1 (OS1)

Permanent allocation of a channel to a voice call (conversational) without any multiplexing capability.

Operational Scenario 2 (OS2)

Permanent allocation of a channel to a voice call (conversational traffic class) and multiplexing of best effort data from the same user (background traffic class).

5 Operational Scenario 3 (OS3)

Permanent allocation of a channel to a voice call (conversational traffic class) and multiplexing of best effort data from different users (background traffic class).

10

Operational Scenario 4 (OS4)

Allocation of a channel to more than one voice user (and/or data users) in a dynamic manner.

15

Various attempts have already been made to provide radio access bearers aligned with both GERAN and UTRAN. These systems have however suffered from a number of drawbacks.

20 One proposed solution provides a system which does not reuse circuit switched traffic channels. The distinguishing feature of a circuit switching system is the exclusive use of a channel of preset bandwidths which is dedicated to the use of two users for the duration of a call. For example in the radio access network of the Global System for Mobile communications (GSM) the bi-directional circuit
25 switching channel is reserved for each call. The transmission capacity of the bi-direction channel is the same in both directions i.e. uplink and downlink. Since during a voice call channels are active for only about 40 to 50% of the time this is an inefficient use of the channel.

30 In addition no diagonal interleaving has been provided in the transfer of information. This reduces the effectiveness of error correcting codes and makes data loss more likely.

Furthermore proposed solutions do not provide a half-rate packet switched channel. Packet switching is based on the idea of message switching. A message or group of data is formed with a header and end-of-message portion. The message is stored in a buffer at each switch where the header is decoded
5 and the next node in a route is determined. A half-rate packet switched channel allows each channel to be divided into two sub-channels thereby providing increased traffic potential. This makes use of so-called half-rate codecs (i.e. a codec giving toll quality speech at 8kb/s) which helps improve spectral efficiency or user density for the allotted channel spectrum.

10

In a similar manner no quarter rate circuit switched channel has been provided. This has the drawback that the advantages of quarter rate codecs which have been developed cannot be utilised.

15 Another drawback of prior systems has been the lack of associated control channel (ACCH) considerations. These control channels carry signalling or synchronisation data and are well known in telecommunications systems. Four categories of control channels are used. These are known as the broadcast control channel (BCCH), the common control channel (CCCH), the stand alone
20 dedicated control channel (STDCCH) and the associated control channel (ACCH). These ACCHs will be described in more detail hereinbelow.

It is therefore an object of the present invention to provide GERAN radio access bearers which at least partly accommodate the requirements listed
25 above. Advantageously the present invention has as a further object to at least partly avoid the drawbacks provided by other prior GERAN radio access bearers.

According to one aspect of the invention there is provided a communications
30 system comprising a first station capable of communication with a second station over a wireless channel, data being carried over the wireless channel in superframes, each superframe comprising a plurality of frames and each frame comprising a plurality of timeslots;
the system having:

a first mode of operation in which a full rate data channel for circuit switched communications is defined by the allocation to that data channel of corresponding time slots in each frame;

5 a second mode of operation in which two half rate data channels for circuit switched communications are defined by the allocation to each of those data channels of an equal number of corresponding time slots of frames in each superframe; and

10 a third mode of operation in which four quarter rate data channels for circuit switched communications are defined by the allocation to each of those data channels of an equal number of corresponding time slots of frames in each superframe.

According to a second aspect of the invention there is provided a communications system comprising a first station capable of communication
15 with a second station over a wireless channel, data being carried over the wireless channel in superframes, each superframe comprising a plurality of frames and each frame comprising a plurality of timeslots;

the system having a mode of operation in which a data channel for circuit switched communications is defined by the allocation to that channel of
20 corresponding time slots of some of the frames of each superframe, and a data channel for packet switched communications is defined by the allocation to that channel of corresponding time slots of other of the frames of each superframe.

Preferably equal numbers of time slots in each frame are allocated to the data
25 channel for circuit switched communications and the data channel for packet switched communications. Alternatively, half or a quarter of the number of slots that are allocated to the data channel for packet switched communications may be allocated to the data channel for circuit switched communications.

30 The data channel for circuit switched communications may be a half rate data channel or a quarter rate data channel. The data channel for packet switched communications may be a half rate data channel.

Control data for control of the data channel for packet switched communications is preferably carried by the data channel for circuit switched communications. That control data may be for control of transmission power and/or handover of the channel. The control data may comprise a fast access
5 control channel and/or a slow access control channel.

The data channel for circuit switched communications may be a conversational channel. The data channel for circuit switched communications may be a background channel. The data channel for packet switched communications
10 may be allocated time slots during periods when the data channel for circuit switched communications is relatively inactive, for example during lulls in speech data being carried by means of the data channel for circuit switched communications.

15 In the above aspects of the invention a data channel for circuit switched communications may carry data as a circuit switched connection or otherwise. The circuit switched channel is preferably capable of operation via a circuit switched core network of the communication system

20 According to a third aspect of the invention there is provided a communications system comprising a first station capable of communication with a second station over a wireless channel, data being carried over the wireless channel in superframes, each superframe comprising a plurality of frames and each frame comprising a plurality of timeslots;

25 the system having:

a first mode of operation in which a full rate data channel for packet switched communications is defined by the allocation to that data channel of corresponding time slots in each frame;

30 a second mode of operation in which two half rate data channels for packet switched communications are defined by the allocation to each of those data channels of an equal number of corresponding time slots of frames in each superframe.

The or each full or half rate data channel for packet switched communications may be a streaming, interactive or background channel. The or each full, half or quarter rate data channel for circuit switched communications may be a conversational channel.

5

The system may be operable according to the GSM specification or a derivative thereof, such as the GERAN system.

10 The wireless channel preferably carries data by means of 8-fold phase shift keyed modulation (8PSK).

Embodiments of the present invention provide several advantages over prior solutions. Firstly the radio access bearers are compatible with and thereby fulfil the design requirements of release 2000. This represents the next generation
15 of telecommunication networks.

Secondly the reuse of already specified channel coding of adaptive multi-rate (AMR) speech traffic channels for conversational traffic classes and circuit switched data traffic channels for streaming traffic classes is provided for.

20

Thirdly embodiments of the present invention allow circuit switched and packet switched channels to be multiplexed within the same time slot. This enables the conversational and interactive traffic classes to coexist within the same time slot.

25

Fourthly embodiments provided for a quarter rate circuit switched traffic channel thus taking advantage of quarter rate codecs which are available.

30

Fifthly embodiments of the invention allow for the reuse of already specified associated control channel of circuit mode (in particular slow associated control channels (SACCH) and fast associated control channels (FACCH) for conversational and streaming traffic classes.

Furthermore embodiments provide that when packet data of the same user is multiplexed within the silent periods of a speech traffic channel (conversational traffic class) the packet data will use for control the SACCH and FACCH channels of the speech traffic channel as well.

5

Still further embodiments provide half rate packet switched traffic channels to increase multiplexing capabilities.

Embodiments of the present invention will now be described hereinafter with reference to the following drawings in which:

10

- Figure 1 shows a user plane protocol stack suitable for use in GERAN;
- Figure 2 shows a full rate traffic channel;
- Figure 3 shows a half rate traffic channel;
- Figure 4 shows a quarter rate traffic channel;
- Figure 5 illustrates FACCH mapping on full rate channels;
- Figure 6 shows FACCH mapping on half rate channels;
- Figure 7 shows FACCH mapping on quarter rate channels;
- Figure 8 shows a full rate packet channel;
- Figure 9 shows a half rate packet channel;

25

In the drawings like reference numerals refer to like parts.

30

The protocols used to create the radio access bearers are built as in UMTS where combinations of different modes of protocols in one single stack provide a large set of bearers. The protocol stack to be used is depicted in Figure 1 each layer of which includes different modes. The different modes of each layer are identified below.

Packet data convergence protocol (PDCP)

Transparent with removal of RTP/UDP/IP header. Bearer services can be transparent or non-transparent. Transparent services provide error protection only via forward error correction (FEC). On the other hand non-transparent services have the additional protection of automatic repeat request (ARQ). This is provided in the radio link protocol which gives improved data integrity.

Non-Transparent with header adaptation (header stripping or header compression).

Non-transparent without header adaptation.

Radio Link Control (RLC)

Transparent

Unacknowledged

Acknowledged

Media Access Control (MAC)

Dedicated: no user identification is included allowing only one user per channel. However whenever this continuous transmission (DTX) occurs, data packets from the same user can be transmitted. The function of the DTX is to suspend radio transmission during silence portions in a speech channel. Normally this is used to help prevent interference and increase capacity of the system. By transmitting data packets during the silent portions system capacity can be further increased.

Shared: the same channel can be shared between several users.

Physical (PHYS)

Modulation: a modulation process is used to convert channel coded speech or data into a type suitable for transmission over the radio channel. Effectively modulation makes it possible to transmit binary information on analogue carriers. During modulation a bit or group of bits is translated into rapid changes in state such as changes in amplitude or frequency. Presently Gaussian minimum shift keying (GMSK) and eight phase shift keying (8PSK) are defined for use with the GERAN. Speech transmission uses only GMSK whereas data can be conveyed using 8PSK or GMSK modulation. In phase shift modulation the phase of a signal is shifted differently relative to the previous phase (e.g. plus 90° for zero and plus 270° for one).

Channel coding: because of electromagnetic interference encoded speech and data signals transmitted over the radio interface must be protected from errors. Convolutional encoding and block interleaving are used to achieve this protection. In particular two different error protection mechanisms which perform convolutional encoding exist within the GSM specification. Unequal error protection (UEP) which treats the bits of a signal with different channel coding depending upon the class of bit (class 1a bits are most sensitive to bit errors, class 1b bits are moderately sensitive whilst class 11 bits are least sensitive to bit errors). Equal error protection (EEP) uses the same channel coding for all data information.

Channel rate: a traffic channel is used to carry the speech and data traffic. Traffic channels are defined using a 26 frame multi-frame as will be described in more detail herein after. Out of the 26 frames 24 are used for traffic. These are the full rate traffic channels. Some half rate and quarter rate channels are also provided. It will be understood that the present invention is not limited to frames and multi-frames of this configuration.

Interleaving: as mentioned above interleaving is used to protect data from errors occurring during transmission. After encoding interleaving steps are carried out to interleave the various signal bits with encoding indices to form an interleaved sequence. If an error occurs in part of that sequence the remainder can be utilised to reconstruct the correct data. Interleaving can be diagonal

(diag) or rectangular (rect) and different interleaving depths can be used (19, 8, 4, 2). The higher the interleaving depth the better the link level performance however the longer the delay.

- 5 Radio access bearers according to the present invention are selected from among the combinations of the different layers on offer.

Mapping of the radio access bearers onto the physical layer can use two kinds of traffic channels as described above. These are the packet channels (PCH)
10 and circuit switched channels (TCH). User data is not the only information which has to be carried through these channels over the air interface. Signalling messages must also be conveyed. These allow the network and MS to discuss the management of several issues such as resource and handover. When traffic is ongoing this signalling is done through the associated control
15 channel (ACCH). However because of different requirements the way in which ACCHs are implemented differs for packet or circuit switched traffic channels. Various ACCHs are well defined for packet and circuit switched channels and some of these are identified and described below. In addition ACCHs for GERAN radio access bearers implemented in accordance with the present
20 invention are described.

ACCHs are bi-directional channels. In the downlink they carry control commands from the base station to the mobile station (MS) to control its transmitted power level. In the uplink they carry the status of the MS to the
25 base station. SACCH is used in signalling the layer at least for measurement results during transmission from the MS to the network. The SACCH has the particularity that continuous transmission must occur in both directions. For that purpose in the MS to network direction measurement result messages are sent at each possible occasion when nothing else has to be sent. Similarly
30 system information type 5, 6 and optionally 5 bis and 5 ter messages as are known in the art are sent in the network to MS direction in UI frames when nothing else has to be sent. SACCH is used for non-urgent procedures, mainly for the transmission of the radio measurement data needed for handover decisions.

In every SACCH downlink block there exists ordered MS power level and ordered timing advance information. In every SACCH uplink block there exists actual MS power level and actual timing advance information.

5

In addition the SACCH conveys messages detailed in Annex A. Each SACCH block contains 184 information bits which are 456 bits encoded and interleaved over four bursts. One SACCH cycle is 480 ms. In other words the timing advance, power level and measurement reports can be updated every 480 ms.

10 It will be understood that the present invention is not limited to blocks and bits of this configuration.

The FACCH (also known as main dedicated control channel (DCCH)) facilitates urgent action such as handover commands and channel reassignment in
15 intracell handovers. It is transmitted by pre-empting half or all of the information bits of the bursts of the traffic channel (TCH) to which it is associated.

There are four alternative varieties of bursts used for transmission in GSMs.
20 These are the normal burst, F burst, S burst and access burst. Of these the normal burst is used to carry data and most signalling. It has a total length of 156.25 bits consisting of two 57 bit information bits, a 26 bit training sequence used to synchronise the receiver with incoming information and to avoid the negative effects produced by multi-path propagation, 1 stealing bit for each
25 information block (which indicates to the receiver whether information carried by a burst corresponds to traffic or signalling data), 3 tail bits at each end (used to cover the periods of ramping up and down of a mobile's power) and an 8.25 bit guard sequence (used to avoid a possible overlap of two mobiles during ramping time). FACCH is used for various purposes such as call establishment
30 progress, handover, subscriber authentication, DTMF, notification (for VGCS and VBS – instead of NCH) and paging (instead of PCH).

FACCH can carry messages which are described in Annex A. Each FACCH block contains 184 information bits (or data bursts), these are 456 bits encoded

as SACCH, the interleaving depending on its associated channel (full rate or half rate).

5 The enhanced fast associated control channel (E-FACCH) is a fast associated control channel introduced for ECSD. Each E-FACCH block contains the same information as FACCH (184 bits) and uses GMSK modulation. But the E-FACCH is mapped on full consecutive bursts instead of eight half bursts for FACCH in full rate.

10 The enhanced in-band associated control channel (E-IACCH) is the in-band E-TCH/F associated control channel introduced for the fast power control (FPC) in ECSD. The BSS indicates to the MS via the SACCH channel the use of the FPC. The power control information is sent every FPC reporting period of length 4TDMA frames (20 ms). The three information bits are coded into 24
15 bits which are mapped on the stealing symbols of four consecutive normal bursts.

Even if the fast power control is activated, the normal power control (via SACCH) is always running. However the MS then ignores the power level
20 commands from SACCH.

The above-mentioned ACCHs are associated with circuit switched traffic channels. The following two ACCHs are associated with packet traffic channels.

25

Packet associated control channel (PACCH) conveys signalling information related to a given MS. The signalling information includes for example acknowledgements and power control information. The PACCH carries also resource assignment and reassignment messages, comprising the assignment
30 of a capacity for PDTCHs and for further occurrences of PACCH. The PACCH shares resources with PDTCHs that are currently assigned to one MS. Additionally an MS that is currently involved in packet transfer can be paged for circuit switched services on PACCH. The messages which can be sent on a PACCH are listed in Annex A.

The PACCH is bi-directional. Each block contains 184 information bits which are 456 bits encoded and interleaved over four bursts (same coding as SACCH). Nevertheless PACCH does not have continuous transmission as
 5 SACCH does.

Because of this continuous transmission a continuous update timing advance mechanism has been defined in GPRS. The timing advance can be updated through a channel of its own. This is called the packet timing advance control
 10 channel (PTCCH). A MS in packet transfer mode will be regularly requested to send random access bursts to the uplink to allow estimation of the timing advance. PTCCH is then used in the downlink to transmit timing advance information updates to several MSs. Table 1 below sets out the various control channels.

15

		Circuit Channels		Packet	
Measurement Reports	Channel	SACCH		PACCH	
	Update	480 ms		only if MS has to (i.e. NETWORK_CONTROL_ORDER = NC1 or NC2) rate controlled by NC_REPORTING_PERIOD_T (min = 480ms / max = 6144ms)	
Timing Advance	Channel	SACCH		PTCCH	PACCH
	Update	480 ms		1920ms	20ms - free
Power Control	Channel	SACCH	E-IACCH	PDTCH (RLC/MAC Header)	PACCH
	Update	480 ms	20ms	20ms - free	20ms - free
Handover		FACCH		PACCH no handover as such but cell reselection can be network or MS controlled	

Table 1. ACCH functions

The table shows the associated control channels and update times for the
 20 various control procedures for both circuit switched and packet switched traffic channels.

In a manner somewhat similar to the above-mentioned existing examples GERAN radio access bearers make use of two different kinds of traffic channels. These are the circuit switched and packet switched channels.

- 5 Circuit switched channels can be used for streaming and conversational traffic classes where constant real time data flow is required. There is of course some difference between the delay requirements of these two classes as the streaming traffic type has more relaxed requirements. From the physical layer point of view it means that the streaming traffic type allows longer interleaving
10 to be used.

The manner in which SACCH is mapped onto a physical channel does not depend upon the modulation used for data transfer neither upon traffic class. As mentioned above in respect of existing traffic channels (TCHs) the SACCH
15 will be mapped over four GMSK bursts.

The proposed SACCH mapping is depicted in Figure 2 which follows well known mapping procedures. The data burst modulation can be either GMSK or 8PSK.

20

Figure 2 represents a multi-frame (or superframe) 20 which defines the full rate traffic channel (TCH/F). Each multi-frame comprises a group of 26 TDMA frames 21₀₋₂₅. Since the radio spectrum is a limited resource the bandwidth is divided up via frequency division multiple access (FDMA) and time division
25 multiple access (TDMA) as is well known in the art. In particular FDMA involves the splitting by division of the 25 Mhz bandwidth into 124 carrier frequencies spaced 200 khz apart. Each of these is then divided in time via a TDMA scheme. The basic unit of time in the TDMA scheme is denoted as a burst period and lasts approximately 0.577 ms. Each TDMA frame 21₀₋₂₅ is
30 divided into eight of these burst periods 22. Each TDMA frame 21₀₋₂₅ therefore consists of eight burst periods 22 which form a basic unit for logical channels. One physical channel is one burst period 22 per TDMA frame 21. The channels are defined by the number and position of that corresponding burst period. Throughout the following description the term "multi-frame" will be used

and is to be understood as a superframe, that is, a frame made up of multiple TDMA frames. Likewise the phrase "burst period" will be understood to represent a timeslot in the TDMA frame.

- 5 Each of the eight burst periods 22 making up a TDMA frame comprises a 156.25 bit normal burst including two data bursts as described herein above.

Out of the 26 frames 21, 24 are used for traffic and can transmit data, one, the SACCH frame 23 is used for the SACCH. The final frame 24 is unused and is
10 idle. In speech applications, the digitised speech is typically compressed using a certain speech coding method before it is transmitted over the radio interface. The amount of coded speech depends on the target speech quality and on the efficiency of the speech coding method. The coded speech is usually transmitted in speech frames, and a speech frame typically corresponds
15 approximately to the duration of four TDMA frames. Within a full rate channel 6 speech frames (120ms) correspond to the duration of 26 TDMA frames (24 for speech + 1 for SACCH + 1 for Idle). The speech frames are channel coded with a suitable channel coding method; the choice of the channel coding method is usually affected by the transmission data rate of the communication
20 channel reserved for the call. For full rate channel the number of bits of a channel coded speech frame is typically equal to or less than the number of bits carried by four radio bursts. Interleaving depth, which means over how many radio bursts a certain coded data frame is mapped, depends typically also on the transmission data rate of the communication channel.

25

Known half rate traffic channels (TCH/H) are depicted in Figure 3 which also follows existing SACCH mapping. Two sub-channels 30, 31 are shown each provided via a respective multi-frame 32, 33. Each of these multi-frames (or superframes) includes 26 TDMA frames however the sub-channel in each is
30 provided via a burst period (T) in every other TDMA frame 21. In this case the SACCH for the sub-channel 31 makes use of the 25th frame 21₂₅ which would otherwise be idle.

A quarter rate traffic channel (TCH/Q) for use with circuit switched traffic channels is depicted in Figure 4. Four sub-channels 40, 41, 42, 43 are provided each of which is formed by a burst period T approximately every fourth TDMA frame. In order to provide a SACCH for each of the sub-channels one burst period is reserved once in every two multi-frames. Because of this the conditions required in order to transmit a satisfactory data rate over the air interface makes use in indoor environments and microcells preferable. Of course it will be understood that the present invention is not limited to such environments. In such an environment the user mobility is naturally reduced and therefore the SACCH rate can be decreased without any harmful effect on performance.

As seen in Figure 4 the SACCH for sub-channel zero 40 is provided in TDMA frame 21₁₂ of multi-frame 44₀. The following multi-frame 44 of TDMA frames for that channel does not include a SACCH burst period. Likewise for sub-channel 1, 41 which is formed by multi-frames 45₀ and 45₁ which provide TDMA frames 0 to 51 the SACCH period is in TDMA frame 21₃₈. For sub-channel 2, 42 the SACCH period occurs at TDMA frame 21₂₅ of the multi-frame 46₀. There is no SACCH period required in multi-frame 46₁. In sub-channel 3, 43 the SACCH period occurs in TDMA frame 21₅₁ in the multi-frame 47₁. There is no SACCH period provided in the multi-frame 47₀.

The provision of these four sub-channels requires no extra TDMA frames to be allocated other than pre-existing SACCH and other idle channels.

Since FACCH is involved in delay sensitive mechanisms such as assignment, notification, paging, handover or even in the transmission of ETMF signals, delay requirements can not be relaxed. For instance even if handover probability is quite low (for example in a good environment and with a user having a reduced mobility), it does not mean that FACCH delays can be increased. Actually other mechanisms using FACCH still have to be carried out and longer delays could cause problems in such situations. Thus the FACCH is based on an existing stealing mechanism where the pre-emption can take place at two different levels. These are the frame level where each FACCH

block replaces data frame(s) and the Burst level where each FACCH block replaces four consecutive data burst by four GMSK burst (in ECSD only)

5 The way traffic is effected depends on the interleaving used. In ECSD where relaxed delay requirements allow long interleaving, the stealing mechanism occurs at a burst level (four consecutive bursts stolen). Each data frame is then only slightly affected while the adjective fast of FACCH remains meaningful. When speech is carried the stealing mechanism occurs at a frame level. Data frame(s) are then simply lost.

10

Table 2 below makes a short comparison between the two stealing mechanism possibilities.

	Steal Bursts	Steal Frame(s)
FACCH Interleaving	fixed - 4 bursts	same as TCH one
FACCH Modulation	GMSK	same as TCH one
Effect on data	clipping / reduced quality	clipping
FACCH Delay	Fixed	depends on the TCH interleaving

Table 2. Stealing Mechanisms

- 5 The method of providing the FACCH is dependent upon the type of channel from which the stealing mechanism operates. These will either be data channels or speech channels.

10 A full rate data channel could either use 8PSK or GMSK modulation. For both of them existing solutions are included in GSM specifications and therefore are reused for GERAN. Note that when 8PSK modulation is used, the question which modulation to use to transmit FACCH arises. ECSD studies have shown that taking into account the performance results and the robustness of the FACCH identification the preferred solution is to map the FACCH over four full
15 consecutive GMSK bursts.

A half rate data channel can only use GMSK modulation in order to reuse existing solutions included in GSM specifications. New 8PSK half rate data channels could be used but are not preferable. On the other hand a full rate
20 speech channel can either use 8PSK or GMSK modulation. For GMSK modulation the FACCH mapping follows existing solutions described in GSM specifications (stealing frames). For 8PSK modulation the stealing mechanism can take place at two different levels (burst or frame) as shown in Figure 5. A comparison of both mechanisms is made in Table 3.

FACCH	Steal Bursts	Steal Frame
Modulation	GMSK	8PSK
code-rate	0.4	0.14
interleaving depth	4	8
effect on speech	40ms of reduced quality (enough channel coding to recover data)	20ms clipping

Table 3. FACCH stealing mechanism comparison for 8PSK FR Channels

Figure 5 shows a part of multi-frame 50 for a full rate speech channel which consists of consecutive TDMA frames 51₀₋₁₇. Each formed by eight burst periods 52 or timeslots. Each burst period consists of 156.25 bit as described above. These include two 57 bit information bits otherwise known as two 57 bit frames 53 or data bursts. Thus each timeslot 52 includes two 57 bit data bursts 53 each positioned at a corresponding portion of the timeslot 52. Put another way each 156.25 bit burst period includes two 57 bit frames 53. When an urgent action requires rapid handover or channel reassignment the FACCH can either steal four consecutive burst periods in order to provide the data to control such urgent action or can steal eight bit frames from consecutive burst periods. In the case of stealing bit frames a diagonal interleaving policy is adopted to maintain information integrity. By stealing bit frames (or data bursts) rather than whole burst periods (or time slots) in this way the effect of audible speech being transferred on the open channel can be minimised as may be seen more clearly in Table 3.

Figure 6 illustrates a stealing mechanism for use with a half rate speech channel. For such a channel either 8PSK or GMSK modulation techniques are available. For GMSK modulation FACCH mapping can follow existing mapping solutions as described in GSM specifications as is well known.

For 8PSK modulation the stealing mechanism necessary to provide the FACCH can take place at two different levels (burst or bit frame) as shown in Figure 6. Figure 6 shows a part of multi-frame 60 consisting of a stream of consecutive

TDMA frames 61₀₋₁₇ each of which includes eight burst periods 62 (or time slots). For a half rate channel the channel will be divided into sub-channels each of which sub-channels will consist of burst periods in the same time slot in approximately every other TDMA frame. In Figure 6 the channel transfers speech using the burst periods 61₀₋₃. When an urgent action occurs which requires rapid handover or channel reassignment the FACCH can optionally steal four consecutive bursts 63₀₋₀ on consecutive frames or non-consecutive frames. In stealing consecutive bit frames the two frames from each of two consecutive burst periods are utilised. In the case of stealing frames a diagonal interleaving policy is adopted where possible. Table 4 shows the effects on speech of the three separate stealing mechanism and also sets out their other characteristics.

FACCH	Steal Bursts	Steal Frames	Steal non consecutive Frames
modulation	GMSK	8PSK	8PSK
code rate	0.4	0.14	0.14
interleaving depth	4	6	8
effect on speech	60ms clipping (not enough channel coding to recover data)	40ms clipping	20ms clipping + 20ms clipping
Other			delay +20ms

Table 4. FACCH stealing mechanism comparison for 8PSK HR Channels

Figure 7 illustrates the stealing mechanism for a quarter rate speech channel. The preferable modulation which fits two quarter rate channels is the 8PSK modulation. The stealing mechanism can take place at two different levels (burst or frame) as shown in Figure 6. In order to increase the interleaving depth (thus link level performance) one solution to consider is to steal two non-consecutive frames. A comparison of the three mechanisms is made in Table 5.

FACCH	Steal Bursts	Steal Frames	Steal non consecutive
-------	--------------	--------------	-----------------------

			Frames
modulation	GMSK	8PSK	8PSK
code rate	0.4	0.14	0.14
interleaving depth	4	5	8
effect on speech	100ms clipping (not enough channel coding to recover data)	80ms clipping	20ms clipping + 20ms clipping + 20ms clipping + 20ms clipping
other			delay +60ms

Table 5. FACCH stealing mechanism comparison for 8PSK QR Channel

Figure 7 shows a part of multi-frame 70 which is part of an ongoing information stream carrying speech traffic. The multi-frame consists of a stream of consecutive TDMA frames 71₀₋₁₇. For a quarter rate channel the channel will be divided into sub-channels each consisting of burst periods in the same time slot in approximately every fourth TDMA frame (in fact in TDMA frames 71_{0,4,8,13,17}). When an urgent action necessitates rapid handover or channel reassignment the FACCH can optionally steal four consecutive bursts from the sub-channel (i.e. the burst periods from TDMA frame 71_{0,4,8,13}) or consecutive frames from the consecutive burst periods (i.e. the second frame from the burst period in TDMA frame 71₀, both frames from the burst periods in TDMA frame 71_{4,8,13}, and the first frame from the burst period in TDMA frame 71₁₇ or non-consecutive frames from consecutive burst periods (which would require more TDMA frames than shown in Figure 7). Effects and characteristics provided by the FACCH stealing mechanism for the quarter rate speech channel are shown in Table 5.

ACCHs associated to packet traffic channels (PACCH) differ from ACCHs associated to circuit switched traffic channels. The PACCH requires explicit resources allocation while SACCH is implicitly given one time slot every 120 ms (26 TDMA frames). Besides there is no FACCH approach needed since every single packet can carry either user data or signalling, the different being made through the RLC/MAC headers.

For background and interactive traffic classes where no real time constant data flow is needed PACCH blocks can be inserted anywhere. But when it comes to conversational and streaming traffic classes a constant data flow is required.

5 Unfortunately because of the 52 multi-frame structure the mapping of such traffic type will not provide any free block for PACCH purposes. As an example consider a full rate speech packet traffic channel. On one hand every 52 TDMA frames 12 block are available. On the other hand every 52 TDMA frames (240 ms) 12 speech frames (20 ms) need to be transmitted. Therefore

10 each block shall carry one speech frame. Consequently there is no block available for ACCH. The same occurs when two half rate packet voice users are multiplexed on the same packet traffic channel.

However the timing advance and power control mechanisms do not use the

15 PACCH. In addition since the cell reselection can be MS controlled it is not always necessary to transmit measurement reports in the uplink. One option is therefore a mechanism by which an MS sends a list of desired cell candidates only when handover is required. Consequently a PACCH rate as high as one in every 480 ms may not be needed in packet mode. Thus for the

20 conversational and streaming traffic classes the PACCH should be able to steal one speech block when needed. In order to reduce the effects on the end user perceived quality, PCU could try to fill silent periods with PACCH blocks.

Nevertheless it is awkward to always have to steal voice packets in order to

25 transmit control information. Therefore for conversational and streaming traffic classes the circuit switched approach should be followed as described hereinbelow.

Figure 8 shows a full rate packet channel (PCH/F) 80 which consists of two

30 multi-frames 81_{0,1}. Each multi-frame includes 26 TDMA frames 82₀₋₂₅ and 82₂₆₋₅₁. Each of the TDMA frames includes eight burst periods which are used to carry data (D). A data channel is provided by a corresponding burst period in each of the TDMA frames. In each multi-frame 24 TDMA frames are used to transfer packet switched data D. One TDMA frame is used as the packet

switched traffic control channel (PTCCH) whilst the remaining burst period is left idle.

Figure 9 illustrates a half rate packet channel (PCH/H). Two sub-channels 90, 91 are shown each of which is provided via a pair $92_{0,1}$ and $93_{0,1}$ of multi-frames. Sub-channel 90 is formed by burst periods D in approximately every other TDMA frame 94_{0-51} . Likewise sub-channel 91 is formed via corresponding burst periods D in approximately every other TDMA frame 95_{0-51} . The two sub-channels are constructed so that the burst periods in each are offset from one another. Thus TDMA frame 94_0 is used for sub-channel 90, TDMA frame 95_1 is used for sub-channel 91, TDMA frame 94_2 is used for sub-channel 90 and TDMA frame 95_3 is used for sub-channel 91 etc.

The PTCCH is provided for sub-channel 90 in TDMA frames 94_{12} and 94_{38} . The PTCCH is provided for sub-channel 91 in TDMA frames 95_{25} and 95_{51} . It will be understood by those skilled in the art that although sub-channels 90 and 91 are shown for illustrative purposes as four separate multi-frames $92_{0,1}$ and $93_{0,1}$ they really represent only two interlinked consecutive multi-frames.

Using such a half rate packet channel (PCH/H) allows multiplexing on the same time slot with a half rate circuit switched channel (TCH/H).

Another way to consider a half rate packet channel would be to allocate one every two blocks (for bursts) within a PCH/F. However from the physical layer point of view it would look like a PCH/F and therefore could not be multiplexed with a TCH/H. Packets are mapped by following a granularity of four consecutive bursts. In other words packets can either be four or eight bursts long.

With the above-mentioned full, half and quarter rate channels the following are the possible ways in which channels can be combined onto basic physical channels. Numbers appearing in parentheses after channel designations indicate sub-channel numbers.

- i) TCH/F
- ii) PCH/F
- iii) TCH/H (0) + TCH/H (1)
- iv) TCH/H (0) + PCH/H (1)
- 5 v) PCH/H (0) + TCH/H (1)
- vi) PCH/H (0) + PCH/H (1)
- vii) TCH/Q (0) + TCH/Q (1) + TCH/Q (2) + TCH/Q (3)
- viii) TCH/Q (0) + TCH/Q (1) + TCH/H (1)
- ix) TCH/H (0) + TCH/Q (2) + TCH/Q (3)
- 10 x) TCH/Q (0) + TCH/Q (1) + PCH/H (1)
- xi) PCH/H (0) + TCH/Q (2) + TCH/Q (3)

Figure 10 shows how the various modes of a user plane protocol stack suitable for conversational traffic and use with the GERAN are configured. The protocol stack 100 includes a packet data convergence protocol (PDCP) layer which corresponds to the application layer of the well known UMTS stack model and contains three modes 102, 103 and 104 which are non-transparent with header removal, non-transparent with header adaptation and framing and non-transparent with framing respectively. The transparent modes provide error protection only via Forward Error Correction (FEC). On the other hand non-transparent modes provide additional protection via ACK (ACKnowledge mode). The RTP/UDP/IP header can be removed or adapted.

The protocol stack 100 also includes a radio link control (RLC) layer 105 which corresponds to the UMTS stack network layer and includes modes 106, 107 and 108 which are transparent with LA-ciphering, unacknowledged with segmentation, link adaptation (LA) and ciphering and unacknowledged with segmentation, link adaptation (LA), forward error correction (FEC) and ciphering respectively.

The protocol stack also includes a media access control (MAC) layer 109 which includes two modes 110 and 111 which are for dedicated and shared channels respectively. For dedicated channels no user ID is included allowing only one user per channel however when DTX occurs data packets from the same user

can be transmitted. In shared mode the same channel can be shared between several users.

The protocol stack also includes a physical layer (PHYS) 112 which includes
5 two modes 113 and 114 which are for circuit switched (TCH) and packet
switched channels (PCH) respectively. The physical layer allows for GMSK or
8PSK modulation in order to convert channel coded speech or data into a type
suitable for transmission over the radio channel. Various channel coding
strategies can also be implemented to protect data integrity such as UEP and
10 EEP. Rectangular and diagonal interleaving at a depth of 2, 4, 8 or 19 can also
be introduced to aid data integrity.

Table 7. Conversational Radio Access Bearers

The first radio access bearer A supports operational scenario (OS) 1 which is the permanent allocation of a channel to a voice call (conversational traffic class) without multiplexing capabilities. This provides optimised adaptive multi-write (AMR) speech reusing the data link layer from GSMCS mode. The mapping follows Figures 2, 3 or 4 depending upon the channel rate, i.e. full rate TCH/F, half rate TCH/H or quarter rate TCH/Q. Various coding strategies such as UEP, TCH/AFS, E-TCH/AFS, E-TCH/AHS and E-TCH/AQS can also be provided for. This radio access bearer utilises FACCH and SACCH signalling mapping as described hereinabove.

10

The second radio access bearer B of Table 1 supports OS1 and also OS2 which is the permanent allocation of a channel to a voice call (conversational traffic class) and multiplexing of best effort data from the same user (background traffic class). This bearer B is provided by using the transparent mode 102 in the PDCP layer 101 with header removal, transparent mode 106 in the RLC layer 105 with link adaptation (LA) and ciphering dedicated mode 110 in the MAC layer 109 and circuit switched mode 113 in the physical layer 112. The bearer provides optimised AMR speech. The coding and signalling are equivalent to the bearer A but the protocol stack is different allowing for the support of OS2 thanks to the MAC layer. The mapping follows Figures 2, 3 or 4 depending upon the channel rate. It is possible to fit best effort data packets from the same user within silent periods.

20

The third radio access bearer C of Table 6 likewise supports OS1 and OS2. This bearer is provided by using the non-transparent mode 103 in the PDCP layer 101 with header stripping as an adaptation and including framing which includes segmentation and addition of a header. The transparent mode 106 in the RLC layer 105 with LA and ciphering and dedicated mode 110 in the MAC layer 109 are also used. The circuit switched mode 113 is utilised in the physical layer in either full, half or quarter (TCH (F/H/Q)) rate depending upon the channel rate required. The bearer provides optimised AMR speech with header stripping. In addition to SACCH and FACCH control channels the bearer uses an embedded associated control channel (MACH) as described in

25

30

Finnish Patent application number 20000415 filed on 23.02.2000, which is incorporated herein by reference. The mapping follows Figures 2, 3 or 4 depending upon the channel rate. It is possible to fit best effort data packets from the same user within silent periods.

5

The fourth radio access bearer D or Table 6 supports OS3 which is the permanent allocation of a channel to a voice call (conversational traffic class) and multiplexing of best effort data from different users. OS4 is also supported which is the allocation of a channel to more than one voice user (and/or data users) in a dynamic manner. The bearer is provided by the non-transparent mode 103 with header stripping and framing from the PDCP layer 101. The unacknowledged mode 107 from the RLC layer 105 is also used which provides segmentation, LA and ciphering. The shared mode 111 from the MAC layer 109 is utilised as is the packet switched mode 114 from the physical layer 112. By configuring the protocol stack in this manner a generic conversational radio access bearer D is produced. The mapping follows the scheme shown in Figures 8 and 9 depending upon the channel rate required. In order to benefit from longer interleaving two speech frames are encapsulated within one radio block.

20 Figure 11 shows the protocol stack 100 for streaming radio access bearers. The protocol stack includes the same modes and layers as those of Figure 10 but the routing and selection of the modes is different. The blocks shown via a dotted line are not used. The data link layer 115 is taken from the GSMCS mode and therefore allows the use of a existing circuit switched data channels.

25 The paths through the protocol stack as indicated by the arrows in Figure 11 are detailed in Table 7. The operational scenarios are not applicable in the context of streaming radio access bearers.

Table 7. Streaming Radio Access Bearers

Five radio access bearers A to E are defined for streaming radio access bearers. The first of these labelled A is provided for optimised streaming reusing the data link layer 115 from the GSMCS mode. The bearer A uses depth 19 diagonal interleaving for a full rate circuit switched traffic channel which can be either GMSK or 8PSK modulated. The coding scheme for these two alternatives is different as are the signalling mapping schemes. When GMSK modulation is used FACCH and SACCH control channels are used together with TCH/F14.4 and F9.6 coding. This is a traffic channel for data transmission specified in the 05.02 GSM specification. The numbers correspond to the bit rate : 14.4 kbit/s and 9.6 kbit/s respectively. When 8PSK modulation is used on the traffic channel FACCH and SACCH control channels are supported together with E-IACCH/F. These allow for E-TCH/F28.8, 32.0 or 43.2 coding to be used. Here the numbers correspond to the bit rate of each coding scheme, i.e. respectively 28.8kbit/s, 32kbit/s and 43.2 kbit/s. These coding schemes are used for ECSD (Edge Circuit Switched Data service) as equal error protection.

The second streaming radio access bearer B utilises the transparent mode 102 in the PDCP layer 101 of the protocol stack. The transparent mode 106 from the RLC layer 105 is also used together with the dedicated mode 110 in the MAC layer 109. The physical layer 112 is configured to provide circuit switched channels using a depth 19 diagonal interleaving policy. By either using GMSK or 8PSK modulation on the channel to retain data integrity various coding and signalling mapping policies can be implemented as may be seen in Table 7. The coding and signalling is equivalent to A but the protocol stack is different configured. The signal mapping follows Figures 2, 3 and 4 depending upon the channel rate.

The third streaming radio access bearer C utilises the non-transparent mode 103 from the PDCP layer of the protocol stack. Additionally the headers are adapted by stripping and then framing is carried out. The protocol path is then configured to use the unacknowledged mode 107 in the RLC layer 105 including segmentation, LA and ciphering. The dedicated mode 110 from layer 109 is also utilised. Various options are then available for channel operation as

set out in Table 7. This provides optimised streaming with header stripping. The mapping follows Figures 2, 3 and 4 depending on channel rate.

The fourth streaming radio access bearer D provides optimised streaming with header compression. Bearer D utilises the non-transparent mode 103 in the
5 PDCP layer of the protocol stack including header compression and framing. The unacknowledged mode 107 is also used from the RLC layer 105 together with segmentation LA and ciphering. The MAC layer 109 is configured to operate in dedicated mode 110 whilst the physical layer 112 is configured to
10 operate in circuit switched mode 113. The various interleaving, modulating, coding and mapping protocols which can be implemented are shown in Table 7.

The fifth streaming radio access bearer E provides an generic streaming radio access bearer. The protocol stack is configured as shown in Table 7 and Figure 11. The non-transparent mode 103 in PDCP layer 101 is selected and
15 is configured for headers compression and framing. The unacknowledged mode 107 is utilised in the RLC layer 105 together with segmentation, LA and ciphering. The shared 111 is used from the MAC layer 109. The packet switched mode 114 is selected from the physical layer. By configuring the protocol stack in this way the various options for traffic channels set out in
20 Table 7 are available. This bearer utilises PACCH and PTCCH control channels as described hereinabove. The mapping follows Figures 2, 3 or 4 depending upon the channel rates. In order to benefit from longer interleaving two speech frames are encapsulated within one packet. However only one data frame can be encapsulated.

25 Figure 12 shows the protocol stack for interactive radio access bearers. The protocol stack includes the same modes and layers as those of Figure 10 but the routing and selection of the modes is different as indicated via the arrows which indicate the path of the possible bearers. The blocks or modes shown via a dotted line are not used. The paths indicated by the arrows are detailed
30 in Table 8. Only two radio access bearers are provided and these are labelled A and B.

PDCP	RLC	MAC	PHY			Coding	Signalling	OS

Table 8. Interactive Radio Access Bearers

5 The first of these A is produced via mode 103 of PDCP layer 101, which is a non-transparent mode which adapts the header via compression and framing techniques. The acknowledged mode 108 is chosen from the RLC layer 105 together with segmentation, LA and ciphering and backward error correction (BEC). The shared mode 111 of the MAC layer 109 in the protocol stack is

10 also implemented. Packet switched traffic channels are used with full or half rate channels being used depending upon the channel rate required as shown in Figures 2, 3 or 4. PACCH and PTCCH channels can be used as described hereinabove. The reference to operational scenarios is not relevant to interactive access bearers.

15

The second interactive bearer B is implemented in a similar manner however the PDCP mode which is adopted does not use header compression. This

bearer provides a generic interactive radio access bearer. The channel mapping follows Figures 2, 3 or 4 depending upon the channel rate.

Figure 13 illustrates the protocol stack for background radio access bearers. The protocol stack includes the same modes and layers as those shown in
5 Figures 10, 11 and 12 but utilises different modes of them via a different routing method as shown via the arrows. The blocks shown via a dotted line are not utilised. The paths shown by the arrows in Figure 13 are described in more detail in Table 9. Four background radio access bearers A to D are defined.

PDCP	RLC	MAC	PHY			Coding	Signalling	CS	
			Channel	Interleav.	Mod.				
Non Transparent Header Compression Framing	Ack	Dedicated	TCH/F	4 rect	GMSK	EEP	SACCH + FACCH	2	A
	Segmentation				8PSK	EEP	SACCH + FACCH	2	
	LA		TCH/H	4 rect	GMSK	EEP	SACCH + FACCH	2	
	Ciphering BEC				8PSK	EEP	SACCH + FACCH	2	
Non Transparent Framing	Ack	Dedicated	TCH/F	4 rect	GMSK	EEP	SACCH + FACCH	2	B
	Segmentation				8PSK	EEP	SACCH + FACCH	2	
	LA		TCH/H	4 rect	GMSK	EEP	SACCH + FACCH	2	
	Ciphering BEC				8PSK	EEP	SACCH + FACCH	2	
Non Transparent Header Compression Framing	Ack	Shared	PCH/F	4 rect	GMSK	EEP	PACCH + PTCCH	3 - 4	C
	Segmentation				8PSK	EEP	PACCH + PTCCH	3 - 4	
	LA		PCH/H	4 rect	GMSK	EEP	PACCH + PTCCH	3 - 4	
	Ciphering BEC				8PSK	EEP	PACCH + PTCCH	3 - 4	
Non Transparent Framing	Ack	Shared	PCH/F	4 rect	GMSK	EEP	PACCH + PTCCH	3 - 4	D
	Segmentation				8PSK	EEP	PACCH + PTCCH	3 - 4

	Ciphering BEC				8PSK	EEP	PACCH + PTCCH	3 - 4	

Table 9. Background Radio Access Bearers

The first of these A of Table 9 is provided by selecting the non-transparent mode 103 from the PDPC layer 101 together with header compression and framing. The RLC layer 105 is configured using the acknowledged mode 108 which allows for segmentation, LA, ciphering and BEC. The MAC layer 109 is implemented using a dedicated channel structure by selecting mode 110. Circuit switched channels are then used by selecting modes TCH. This fulfils OS2 and provides packet transmission within silent periods of the circuit switched channels. Best effort data (or background) with header compression within OS2 is provided. The control associated to the packet data is carried out by the associated control channels of the speech traffic channel (FACCH and SACCH). Best effort data packets are mapped onto four consecutive bursts.

The second background radio access bearer (B of Table 9) is implemented as shown in Table 9 using the non-transparent mode 104, acknowledged mode 108, dedicated mode 110 and circuit switched mode 113. This also provides packet transmission within silent periods but best effort data (or background) without header compression within OS2. The control associated to packet data is carried out by the associated control channels of the speech traffic channel (FACCH and SACCH). Best effort data packets are mapped onto four consecutive bursts.

The third background radio access bearer (C of Table 9) is implemented using the non-transparent mode 103 of PDPC layer 101, the acknowledge mode 108 of RLC layer 105, the shared mode 111 of MAC layer 109 and the packet switched mode 114 of the physical layer 112. The bearer implements OS3 and OS4 and provides a background radio access bearer with header compression.

The fourth background radio access bearer (D of Table 9) provides a generic background radio access bearer. This is implemented using the non-transparent mode 104 of the PDPC layer 101, the acknowledged mode 108 of the RLC layer, the shared mode 111 of the MAC layer 109 and the packet switched mode 114 of the physical layer 112. The mapping follows Figure 2, 3 or 4 depending upon the channel rate and the bearer supports OS3 and OS4.

The possible associated control channels needed for GERAN have now been described. These depend on the kind of traffic channel used over the interface. For packet traffic channels PACCH clearly fulfils the signalling requirements for background and interactive traffic classes. However when conversational and streaming traffic classes are considered the only way to transmit PACCH is to steal voice packets. The influence on voice quality might be reduced. However since TA and PC updates does not use PACCH and since measurement reports can be limited, PACCH traffic could be reduced. Nevertheless it is advantageous to reuse existing circuit switched traffic channels where more efficient associated control has been defined.

For circuit switched traffic channels SACCH and FACCH accommodate the signalling requirements of streaming and conversational traffic classes.

Embodiments of the present invention take place in GERAN which means that the physical layer is mainly connected to the packet switched core network but can also be connected to the circuit switched core network. Previously there has been on the one hand a circuit switched air interface (TCH + SACCH + idle) connected to a circuit switched core network (through the A interface) and on the other hand a packet switched air interface (PDTCH + PTCCH + idle i.e. PDCH) connected to a packet switched core network (through Gb interface). Embodiments of the present invention allow the circuit switched air interface to be connected to a packet switched core network (through Gb or Iu-ps interfaces), and allow the circuit switched air interface to support packet data (not only TCH) and therefore to be also connected to a packet switched core network (through Gb or Iu-ps interfaces). Thereby one possible combination over the circuit switched air interface will be PDTCH + SACCH + idle. In case of OS2 a possible combination will be TCH + PDTCH + SACCH + idle. Where a communication system according to the present invention can be implemented.

GERAN is used as an example of a system where a communication system according to the present invention can be implemented. The systems and methods described herein according to the invention are not restricted however

to those used in GSM or in EDGE; a system or method according to the invention can be applied also in other radio networks.

GERAN is used as an example of a system where a communication system according to the present invention can be implemented.

It will be understood by those skilled in the art that the present invention is not limited to the above examples but rather modifications could be made without departing from the scope of the present invention.

Annex A – Contents of Associated Control Channels

Associated Control Channels	Messages
SACCH	Measurement Report - Uplink System Information Type 5 - Downlink System Information Type 6 - Downlink System Information Type 5 bis - Downlink System Information Type 5 ter - Downlink Extended Measurement Order - Downlink Extended measurement report - Uplink SID frames in case of DTX
FACCH	Additional Assignment - downlink Assignment command - downlink Assignment complete - uplink Assignment failure - uplink Channel mode modify - downlink Channel mode modify acknowledge - uplink Channel release - downlink Ciphering mode command - downlink Ciphering mode complete - uplink Classmark change - uplink Classmark enquiry - downlink Configuration change command - downlink Configuration change acknowledge -uplink Configuration change reject - uplink Frequency redefinition - downlink Handover access Handover command - downlink Handover complete - uplink Handover failure - uplink Notification/FACCH - downlink RR-Cell Change Order - downlink Paging response - uplink Partial release - downlink Partial release complete - uplink
